Video script: How vision works

Welcome to this dryAMD.uk video where we take a closer look at how vision works.

If you are affected by advanced dryAMD or geographic atrophy, as a patient, a family member or a caregiver, it is important to understand how we see.

For someone with healthy eyes, seeing comes naturally. But how does the eye actually work? Let's take a look at how we see.

Basically, the eye looks like a sphere.

In the front part of this sphere we've got a typically brown, blue or green coloured circle - the iris. It is coloured due to its pigments. It regulates the amount of light that enters the eye through the pupil by controlling its size.

The pupil is the black opening in the centre of the iris. It allows light to enter the inside of the eye reaching the retina.

This is the vitreous humour. It's a clear gel that fills the space between the lens and the retina at the back of the eye. Along with maintaining the shape of the eye, the vitreous humour helps absorb shocks to the eye and keeps the retina properly connected to the back wall of the eye.

Here is the lens, a transparent disc behind the iris and the pupil. The lens helps to focus the light and project it onto the retina. The lens enables the eye to see sharply both near and far.

This part right in the front of the eye is called the cornea. It's the clear dome covering the front of the eye including the iris and the pupil. The cornea helps the eye focus the light, so objects look sharp and clear.

Then there is the sclera. The sclera is the white outer layer of the eye, contrasting with the coloured iris. The sclera provides protection and form to the eye.

Let's look at the back of the eye: There we find the retina, a light-sensitive tissue lining the inner back of the eye.

And there's the optic nerve. This bundle of 100 million nerve fibres carries visual messages as electric impulses from the retina to the visual cortex of the brain.

This small area of the retina is called the macula. It has a diameter of around 5.5 mm. The macula is responsible for the central, high-resolution and colour vision.

In the middle we find a small pit we call the fovea responsible for sharp central vision used for reading and driving.

Now, how does this all work together, so we can actually see what we see? Light enters through the cornea and the pupil into the eye. It then travels through the vitreous humour, the clear gel and falls onto the retina at the back of the eye.

Here it's turned into electric impulses. And these impulses will be carried to the brain by the optic nerve.

In summary, the eye is an organ where different parts work together in complex ways to make us see.

Let's take a look at how this transmission works in more detail.

To do this we have to take a closer look at the macula. Remember? That's the part at the back of the eye that is responsible for the central vision.

When light beams enter the eye and reach the retina, they activate photoreceptors, which convert the light stimulus into electrical signals.

These electrical signals are sent by the photoreceptors to the bipolar cells, and subsequently activate the retinal ganglion cells.

From here the signals travel through the nerve cords of the retinal ganglion cells to the optic nerve, which transmits the information to the visual cortex in the brain. In summary, the retina converts light energy into electric signals.

To understand how the light is transformed into electric signals, we take a closer look at those photoreceptors in the retina.

There are about 126 million receptors in each eye. 6 million in the form of cones, and 120 million shaped as rods. The function of the cones is to detect daylight, colours and fine details. And they mainly manage the central vision. The rods, on the other hand, are good for detecting large moving objects, grey scale, and nightlight. They can process less detail and are there mostly for the peripheral vision.

In summary, rods and cones are photoreceptors in the retina converting light beams into electric impulses.

The highest concentration of photoreceptors in the retina is in the macula. It's the sensitive area, about 5.5 mm in diameter, needed for the central vision.

Here we see in closer details the pit in its centre that is called the fovea. It provides the sharpest and most detailed vision because of the high concentration of cones. Also, the light can pass directly onto the photoreceptors as the inner retinal layers are pushed to either side.

In summary, the fovea is the spot in the macula where vision is the sharpest.

Let's recap the process of seeing in brief:

Light passes through the iris and the pupil. It is focused by the cornea and the lens onto the retina. In the retina, it is focused in the region of the macula. Photoreceptors convert the light into electric impulses that travel through the optic nerve to the visual cortex in the brain.

That's the way we see.

And that's the end of this dryAMD.uk video on how vision works. Make sure to watch other videos on dryAMD.uk to learn more.

End of video script.
